Retrospective Analysis of Periodontal Bone Loss from Orthopantogram X-Ray of Diabetic and Non-Diabetic Patients Visiting Punjab Dental Hospital Lahore

Faiz Rasul¹, Amna Rizvi², Zainab Rizvi¹, Sultan Muhammad Wahid¹, Muhammad Ammar³, Saud Ahmed Cheema³

Abstract

Background: Periodontitis is a dental public health issue evident by interdental bone loss which can be detected by periapical and Orthopantograph (OPG) radiograph. The objective of this retrospective study was to compare bone loss in diabetic and non-diabetic patients visiting Punjab Dental Hospital (PDH) Lahore.

Methods: Bone loss was measured in mesial and distal sites of six teeth i.e. tooth numbers 16, 11, 26, 31, 36, and 46 and a mean score was assigned to each tooth. A score < 2 mm was taken as normal and > 2 mm as bone loss from the cementoenamel junction (CEJ) to interdental bone (Alveolar bone crest). Data was entered into SPSS 22. Variables like age and bone loss were analyzed as mean and SD. A Chi-square test was applied between diabetic, non-diabetic, and independent variables. A p-value of equal to or less than 0.05 was taken as significant.

Results: This study included 101 OPG X-ray, 39 (38.6%) diabetic and 62 (61.4) non-diabetics. The mean age in the diabetic group is 44.28±6.1 and in non-diabetic individuals it is 31.75±9.3. Bone loss in diabetics was as high as compared to non-diabetics. Such as in diabetics, tooth no.16’s mean value is 3.8462 as compared to non-diabetics 2.7258. Significant association between bone loss and status of diabetes was observed in all teeth except tooth no. 31.

Conclusion: Radiographically, bone loss is more common in diabetic individuals than non-diabetic healthy people. First molars have more bone loss than incisors.

Keywords: Orthopantogram X-ray, periodontitis, interproximal bone loss, diabetes mellitus, retrospective analysis.

Introduction

Periodontitis is a chronic inflammatory disease that begins with a buildup of dental biofilm plaque and continues through a disorganized immune response and is commonly started by gingivitis leading to irreversible demolition of the supportive tissues adjoining the tooth together with the alveolar bone. It is a multi-microbial and multifactorial disease with several risk factors such as plaque, smoking, diabetes mellitus and
poor oral hygiene. (1) Diabetes Mellitus (DM) is a metabolic disorder characterized by high blood glucose levels resulting from altered insulin secretion, action or both. (2) Risk for periodontitis is increased two to three times more in diabetic individuals as compared to non-diabetics. (3) Recent meta-analysis suggested that there could be a common physiopathological factor between periodontitis and diabetes mellitus but more prospective studies are needed to investigate the association between these two diseases. (4)

Clinical and radiographic examinations play an important role in the evaluation and diagnosis of periodontal problems such as measurements of clinical attachment level and bone loss. (5) Radiograph provides vital information about the degree of bone loss, continuity, and integrity of the periodontal ligament space. Intraoral periapical (IOPA), Bitewing, and Orthopantomograms (OPG) radiographs are used to evaluate and diagnose bone loss in periodontitis. (6, 7)

OPG is a radiographic procedure that produces a single image of facial structures including maxilla mandible, and their supporting structures. It utilizes intensifying screens, requires less radiation, and saves time thereby making it a potential substitute for intraorad radiography in assessing periodontal conditions. (8) Digital panoramic radiograph is accepted as a method for measuring alveolar bone loss. (5) From OPG x-ray, periodontal diseases can be assessed because of certain radiographic characteristics like bone loss, widening of the periodontal ligament space, and decreased alveolar crest height. (9, 10) From OPG x-ray, early detection of periapical pathologies such as apical periodontitis, periapical cyst, granuloma, and other alterations in the morphological pattern of the alveolar and furcation involvement can be detected. Continuity of the lamina dura in radiographs is the visible and the earliest detectors of periapical pathologies. Any discontinuity or loss of the same can be detected in both conventional and digital imaging. (6) Detailed examination of OPG can give some incidental findings apart from periodontitis. (11) OPG is commonly used due to its several advantages for example: being easy and inexpensive to conduct, and informative regarding jaw morphology and bone density. (12, 13) The purpose of this retrospective study was to determine and compare bone loss (periodontitis) in diabetic and non-diabetic patients retrospectively from the OPG x-ray record of Punjab Dental Hospital. Another objective was to determine the difference in demographic characteristics in both subgroups in context to periodontitis.

Methodology

This study was presented in the Institutional Review Board of de’Montmorency College of Dentistry (DCD) by the principal investigator (FR). Permission was granted through letter no 279 dated 21/01/2021. Retrospective data of the OPG and the patients were taken from Punjab Dental Hospital (PDH) which is a teaching hospital attached with de’Montmorency College of Dentistry (DCD), a major public dental hospital of the Lahore population. Inclusion criteria of the study was diabetic and non-diabetic patients of age range 18 to 50 years having complete information such as age, gender, and OPG x-ray from January 2020 to January 2021. However, patients above 50 years of age and below 18 years of age were excluded from the study along with another comorbidity of any systemic disease like known cases of ischemic heart disease, autoimmune diseases, hypertensive, and syndromic patients. Information of age, gender, diabetes was taken from the indoor register of the outpatient department (OPD) record and Medical Record number was noted. OPG records of these patients who had been advised an X-ray were reviewed and a total of 101 patients records met the criteria.

The principal investigator (FR) assessed the OPG x-rays of 39 diabetic and 62 non-diabetic patients. Bone loss was measured in six indexed teeth, i.e. tooth number 16 (Maxillary right first molar), 11 (Maxillary right central incisor), 26 (maxillary left first molar), 31 (mandibular left central incisor), 36 (mandibular left first molar), and 46 (mandibular right first molar) at mesial and distal sites of all six teeth and a mean score was assigned to each tooth of the patient with the help of an illuminator and a millimeter-scale from the cementoenamel junction to interdental bone (Alveolar bone crest) as narrated by Amaranath et al 2020. (14) Score < 2 mm was taken as normal and above was considered as a confirmation of the presence of periodontal bone loss. Data was entered into SPSS 22. Variables like age and bone loss were analyzed as mean and SD. Frequencies and percentages of variables like gender, residence, socioeconomic position, diabetic and non-diabetic were calculated. A Chi-square test was applied between diabetic and non-
diabetic variables and independent variables. P-value of equal to or less than 0.05 was taken as significant.

Results

The mean age in the diabetic group is 44.2821±6.1 and 31.7581±9.3 in non-diabetic individuals. Females are more in number 69 (68.31%) as compared to males 32 (31.69%). Most of the people 64 (63.4%) have family income < 20000 Pakistani Rupees. Majories of them were non-diabetic 34 (61.4%) as compared to diabetics 30 (38.6%). Around 80 individuals have < 10 years education out of which 52 (65.0%) were non-diabetics and 28 (35.0%) diabetics. Most of the people were partly skilled manual occupations 53 (52.5%) out of which 28 (52.8%) were diabetics and 25 were (47.2%) non-diabetics (Table 1).

Table 2 describing the descriptive statistics in six teeth, tooth #16 has maximum bone loss with a mean of 3.1584 out of 101 around 55.4% have periodontitis, and the remaining are considered as normal because bone loss is less than 2mm. Similarly, other molars 46, 26 and 36 have mean bone loss of 2.6386, 2.7228 and 2.7198 and periodontitis 49.5%, 37.6% and 47.5% respectively. The mean value of bone loss in incisors is of normal range with only 18.8% and 20.8% periodontitis with more than 2 mm bone loss in 11 and 31 respectively.

Table 3 comparisons of two groups are given. In the diabetic group, bone loss is more in all six teeth such as tooth #16 mean value is 3.8462 as compared to non-diabetic group 2.7258, tooth # 26 mean value is 3.8462 as compared to non-diabetic group 2.0161, tooth # 36 mean value is 3.1282 as compared to non-diabetic group 2.4629, and tooth # 46 mean value is 3.4103 as compared to non-diabetic group 2.1532. While in incisors, bone loss in the diabetic and non-diabetic groups lies in the normal range.

Table 4 is depicting relationship of bone loss by tooth and diabetes mellitus. A total of 50 cases in tooth # 46 have a bone loss of more than 2 mm out of which 31(62%) were diabetic and 19 (38%) were non-diabetics. In tooth # 26, a total of 38 cases have a bone loss of more than 2 mm out of which 24 (63.2%) and 14(36.8%) non-diabetics. In tooth # 36, a total 48 cases have bone loss >2mm out of which 23(47.9%) were diabetics and 25(52.1%) were non-diabetics. In tooth # 16, a total of 56 cases have periodontitis out of which 30 (53.6%) were diabetics and 26 (46.4%) non-diabetics. Incisors have a few cases of periodontitis 19 and 21 cases in tooth # 11 and 31 respectively. A significant association was observed in all teeth except tooth # 31.

**Discussion**

Bone loss is a radiological feature of periodontitis and the purpose of this study was to measure bone loss from OPG x-ray in diabetic and non-diabetic individuals. There is a controversy in the literature about the normal interdental space. Some say it is less than 2mm, while others argue that it is less than 1.5 mm.(15) We took 2 mm as normal space in the current study and observed bone loss of more than 2mm in tooth # 16 (55.4%), # 11 (18.8%), # 26 (37.6%), # 36 (47.5%), # 31 (20.8%) and # 46 (49.5%). When these results were compared between diabetics and non-diabetics, bone loss (> 2mm) was observed more in people with diabetes as compared to non-diabetics in all selected teeth except tooth # 31 and # 36. One of the studies reported that people with diabetes have more periodontitis than prediabetics and healthy subgroups.(16)

Marginal bone loss on bitewing radiograph was more common in diabetics 4.7 mm and prediabetics 4.2 mm than in control healthy individuals 2.2 mm. Furthermore, in the current study a maximum bone loss of 3.84 mm was observed in the diabetic group if mean is compared with the study of Alasqah et al., (2018).(17) In the diabetic group bone loss is more in all six teeth such as tooth # 16 mean value is 3.8462 as compared to non-diabetic group 2.7258, tooth # 26 mean value is 3.8462 as compared to non-diabetic group 2.0161, tooth # 36 mean value is 3.1282 as
compared to non-diabetic group 2.4629, and tooth # 46 mean value is 3.4103 as compared to non-diabetic group 2.1532. Whereas in incisors, bone loss in the diabetic and non-diabetic groups lie within the normal range.

In another study Akram et al., reported a more marginal bone loss in poorly controlled diabetic individuals than in non-diabetic with periodontitis and healthy control group. Although in their study mean age group was higher than in the current study, where 55.2 years is in poorly controlled Diabetes with chronic periodontitis, 51.5 years in non-diabetic with periodontitis, and 50.7 years in healthy individuals with mean bone loss 5.2mm, 4.1mm, and 1.6mm in three groups respectively. (18) It is a known fact that patients with well-controlled diabetes mellitus have a periodontal status comparable to systemically healthy individuals.(19)

Plessas et al., 2018, concluded that DM participants had more radiographic alveolar bone loss throughout all the teeth measured and more than a two-fold increase in the risk of having sites with ≥2 mm periodontal destruction compared with non-diabetes subjects. (20) In 2017 Staging and grading of periodontitis was proposed by Tonetti et al., to ensure that the framework incorporates relevant new knowledge within an already functioning. The proposed risk stratification based on well-validated risk factors including smoking, uncontrolled diabetes, clinical evidence of progression or disease diagnosis at an early age, and severity of bone loss relative to patient age. (21)

Another important factor is given in a review by Poudel et al., that most diabetes care providers are not addressing oral health care due to time constraints and limited oral health awareness. Oral health awareness and referral to a dentist for routine visits play an important role which can be provided by diabetes educators (DEs). However, no appropriate oral health training programs and assessment tools exist for DEs. With proper training, non-dental professionals like nurses have successfully incorporated oral healthcare in other settings. (22) Similarly, oral health literacy to diabetic individuals is an important factor as health literacy gaps remain to be addressed in patient understanding the importance of detecting and managing dysglycemia for maintenance of periodontal health, creating opportunities for patient education. (23) Dentists who observe bone loss on x-ray examination, should refer the patient to the physician (diabetes care provider) for diabetes assessment or monitoring. So diagnosis and referral should work both ways; dentist to physician and physician to the dentist. (24)

Age is a risk factor in periodontitis; a study was conducted to determine age-dependent periodontitis in two populations of the United States and Germany in a large population with a sample size of 10713 and 3071 respectively. Recession, periodontal pocket, and clinical attachment loss were taken as parameters to measure periodontitis. Mean clinical attachment loss increased linearly with age in both samples. (25) Mean age in this study is 36.59 (range 18 to 50) while in the diabetic group it is 44.28 and 31.75 in the non-diabetic group. Bone loss is also significantly associated with age however we categorized it into age less than 40 years and above 40 years. Due to poor matching of age in both groups bone loss was significantly associated in diabetic as well as in older age people.

In current study female gender is more common 69 (68.31%) as compared to male 32 (31.69%) which is contrary to the finding of Suphanantachat et al., (2017) in which 11 cases out of 14 (78.5%) were male and 3 out of 14 (21.5%) were female. (26) Akram et al., (2019) analyzed association of periodontitis with diabetes mellitus. In their study three groups were made: Group1 (diabetics with Periodontitis), Group 2 (non-diabetics with Periodontitis) and Group 3 (non-diabetics without Periodontitis). It was reported that male gender is more common as compared to female in all three groups that is 27 out of 32 (84.37%), 25 out of 31 (80.64%), 27 out of 31 (87%) in group1, 2 and 3 respectively. (18)

High risk of Periodontitis is also associated with low socioeconomic status in current study and in Herrera et al., (2018). (27) Finding of a case and control study reported by Rafique et al., (2020) in Karachi shows that low education status is associated with Periodontitis that is similar to finding of the current study. (28)

In the current study bone loss was measured in OPG x-ray while standard radiograph is periapical, and bitewing for measurement of bone loss however findings of bone loss can be comparable to bitewing. (29) Recently a scientific report was published by Krois et al., (2019) to measure bone loss by deep convolutional neural networks (CNNs) to detect periodontal bone loss (PBL) on panoramic dental radiographs. They also compared the results of CNNS to the findings of the senior dentist but did not find it superior in results but comparable with the advantage.
that machine-based technology can reduce the diagnostic efforts of the dentist. (30)

There are some limitations of the study. No numerical data was present to measure the glycemic level of the individuals; retrospectively, only we could find the status of diabetes, either it being present or absent. Secondly, we use OPG x-ray for detection of bone loss instead of bitewing or other advanced images to detect bone loss and exact matching of age could not be possible due to the availability of retrospective data however in comparison bone loss in all selected teeth is reported more in the diabetic population. Further prospective studies in local settings can be carried out by matching age in the case and control group and taking the value of blood glucose or Hb1Ac.

Conclusion

Interproximal bone loss, a pathognomonic sign of periodontitis, is more common in diabetics and older individuals than in non-diabetics and younger individuals. Maximum bone loss was observed in molars as compared to the incisors. In molars, mean bone loss was more than 3mm in diabetics as compared to non-diabetics which have 2.1mm.

Conflict of interest

None of the authors has a conflict of interest or external funding

Acknowledgment

I am thankful to Dr. Jay Balzer, who is retired now from NYU Langone Health; New York, N. Y. USA, for helping in all aspects of our study from concept to writing and reviewing this study. I am also thankful to Dr. Safdar Baig, Associate Professor, Oral & Dental Surgery, Quaid-e-Azam Medical College and Bahawal Victoria / Civil Hospital, Bahawalpur for his help in the analysis of the study.
